Because leptin reduces food intake and body weight, the coexistence of elevated leptin levels with obesity is widely interpreted as evidence of ‘leptin resistance.’ Indeed, obesity promotes a number of cellular processes that attenuate leptin signaling (referred to here as ‘cellular leptin resistance’) and amplify the extent of weight gain induced by genetic and environmental factors. As commonly used, however, the term ‘leptin resistance’ embraces a range of phenomena that are distinct in underlying mechanisms and pathophysiologic implications. Moreover, the induction of cellular leptin resistance by obesity complicates efforts to distinguish the mechanisms that predispose to weight gain from those that result from it. We suggest a framework for approaching these issues and important avenues for future investigation.

Leptin action and the concept of ‘leptin resistance’

Leptin, a polypeptide hormone that is produced by adipocytes in proportion to their triglyceride content, links changes in body energy (fat) stores to adaptive responses in the central control of energy balance [1–4]. By binding to and activating the long form of its receptor (LEPR-B) in the brain, leptin decreases food intake while increasing energy expenditure. Evolutionary considerations, together with a large body of experimental data, indicate that a major physiologic role of leptin is to respond to and defend against reductions of body fat (and thus leptin) that might impair survival and reproductive fitness. Apart from the notable exception that their body fat mass is markedly increased, the phenotypes of humans and rodents lacking leptin or LEPR-B mirror the physiological response to leptin deficiency states as a key regulator of metabolic and neuroendocrine responses to states that are characterized by negative energy balance and weight loss.

Although leptin administration reduces food intake in normal animals, food intake ultimately returns toward normal during prolonged leptin administration, once body fat stores have been substantially depleted [5]. Moreover, treatment with leptin alone (even at very high doses) is ineffective as a means to decrease food intake and body weight in obese animals and humans, although congenital leptin-deficiency states represent an exception to this rule [15]. Indeed, the subset of overweight and obese human subjects who demonstrate the strongest catabolic response to leptin are those at the lower end of the obese body mass index (BMI) range and those with relatively low leptin levels for any given BMI or adiposity level [16,17]. Together with the aforementioned finding of elevated circulating leptin levels in obese subjects (commensurate with their adipose mass) [18,19], these observations have inspired the notion of ‘leptin resistance’ in common forms of obesity [20], analogous to the insulin resistance that contributes to type 2 diabetes and that often coexists with ‘leptin resistance’ in obese individuals. Indeed, similar cellular mechanisms might attenuate the action of both hormones, as detailed below.

LEPR-B signaling

LEPR-B is a type 1 cytokine receptor that, upon leptin binding to its extracellular domain, undergoes a conformational change to activate its associated Jak2 tyrosine kinase [21]. Activated Jak2 promotes the tyrosine phosphorylation of several intracellular residues on LEPR-B (also on Jak2 itself) and each tyrosine phosphorylation site recruits a specific set of downstream molecules to promote specific intracellular signals (Figure 1). LEPR-B contains three distinct tyrosine phosphorylation sites: Tyr985, Tyr1077 and Tyr1138 [22]. Tyr1138 recruits signal transducer and activator of transcription (STAT)3, a latent transcription
factor, which subsequently becomes tyrosine phosphorylated (pSTAT3) by Jak2, enabling its nuclear translocation and promoting its transcriptional effects. Detection of pSTAT3 is used as an important bioassay of LEPR-B signaling in vivo [23]. Similarly, Tyr1077 recruits and mediates the phosphorylation and activation of a related transcription factor, STAT5 [22,24]. Tyr985 recruits the tyrosine phosphatase PTPN11 [protein tyrosine phosphatase, non-receptor type 11 (also called SHP2) which controls extracellular-signal regulated kinase (ERK) activation] and also binds suppressor of cytokine signaling (SOCS3), an inhibitor of LepRb/Jak2 signaling [25,26].

Processes that attenuate LEPR-B signaling
LEPR-B Tyr1138-STAT3 signaling promotes the transcription and accumulation of SOCS3, which binds to Tyr985. SOCS3 binding to Tyr985 attenuates LEPR-B signaling, completing a negative feedback loop [25,26]; indeed, disruption of LEPR-B Tyr985 or CNS SOCS3 in mice decreases food intake and adiposity [27–29]. Furthermore, disruption of the afferent limb of this feedback pathway (i.e., Tyr1138-STAT3) also increases the amplitude and duration of Jak2 activation in cultured cells, and some leptin effects (e.g. on the immune system) are enhanced in Tyr1138 mutant animals [30].

Similarly, protein tyrosine phosphatase (PTP)1B mediates the dephosphorylation of Jak2, limiting the extent of leptin action in cultured cells and in vivo [31,32]. Similar to SOCS3, inactivation of PTP1B in the brain of mice increases leptin signaling and decreases adiposity, implying a physiological role for both proteins to limit signaling via LEPR-B [33,34].

Other pathways also limit cellular leptin action. In peripheral tissues (such as adipose, liver and muscle), obesity promotes both endoplasmic reticulum (ER) stress and a state of chronic low-level inflammation that contributes to insulin resistance; both of these processes might also participate in the attenuation of CNS LEPR-B signaling in obesity [35–37] (Figure 1). For example, obesity is associated with hypothalamic ER stress, which impairs LEPR-B signaling in cultured cells; conversely, attenuation of ER stress improves leptin signaling and leptin action in vivo. Increased activity of inflammatory signaling pathways in the hypothalamus of obese animals can impair leptin signaling both in vivo and in cultured cell models, whereas genetic or pharmacological blockade of inflammatory signals in the brain of obese rodents promotes leptin action and protects against diet-induced obesity (DIO) [35–37]. The story is more complicated, however, as some forms of systemic inflammation (e.g. acute infection, cancer cachexia) promote anorexia and weight loss via mechanisms involving hypothalamic systems that are also targets for leptin action [38].

Thus, SOCS3, PTP1B, ER stress and inflammation represent some of the molecular and cellular mediators that directly attenuate LEPR-B signaling in states of obesity and thus represent mediators of cellular leptin resistance. Although they clearly contribute to diminished leptin action in obesity, the degree to which these responses themselves enable weight gain and/or the maintenance of increased adiposity in obese individuals remains incompletely understood.

Assessing leptin resistance in genetic models
Recent years have witnessed a dramatic increase in the number of genetic mouse models of obesity, and measures of leptin sensitivity (Box 1) have become a routine component of efforts to investigate mechanisms underlying such obesity. Current knowledge indicates that measures of leptin sensitivity are diminished across obese animal mod-
Box 1. Measuring ‘leptin resistance’ in vivo

Assessment of LEPR-B signaling and leptin action in vivo essentially relies on two assays: detection of leptin-stimulated pSTAT3 in the hypothalamus (by immunoblotting or immunohistochemical methods) and responses of food intake and body weight/fat content to leptin administration [22]. The assessment of pSTAT3 levels has emerged as the gold standard experimental marker for cellular LEPR-B action in vivo. The strength of this approach is that hypothalamic pSTAT3 is engaged rapidly and directly by LEPR-B and that most detectable hypothalamic pSTAT3 is typically attributable to leptin action [21,68]. Although hypothalamic pSTAT3 represents a sensitive and specific marker of LEPR-B signaling, STAT3 is not the sole mediator of cellular leptin action [21]. Leptin action in the hypothalamus also mediates signaling by STAT5, ERK, phosphoinositide (PI) 3-kinase, mammalian target of rapamycin (mTOR), AMP-dependent kinase, and potentially other pathways that are partially or completely independent of STAT3 [69–73]. Leptin also controls the membrane potential and firing of its target neurons, and such rapid effects do not involve nuclear STAT3 signaling [74]. Unfortunately, many of these other pathways are more difficult to detect than pSTAT3, can be influenced by factors other than leptin (e.g., PI3 kinase is strongly activated by insulin and mTOR is controlled by amino acid availability) and might be mediated trans-synaptically, which confounds their use as reflectors of cellular leptin signaling [75,76]. Consequently, the field relies primarily on pSTAT3 as the marker for cellular leptin signaling. Despite ongoing uncertainty as to how this reflects the responsiveness of these other leptin-regulated pathways that might (or might not) be affected in obesity. Indeed, because leptin administration produces both acute effects (generally mediated by fast-acting cellular kinase cascades, such as ERK, PI3 kinase and mTOR) and longer-term transcriptional signals (e.g., via STAT3 and STAT5), acute and chronic leptin signals might be affected differently by mediators of cellular leptin resistance [76]. Unfortunately, acute leptin action is poorly studied in chronic obese states. Thus, although pSTAT3 remains a crucial marker for LEPR-B signaling in vivo, additional assays are required to enable the examination of LEPR-B signaling and cellular leptin resistance more completely.

Alterations in LEPR-B or LEPR-B signaling

Animals (or very rarely, humans) with primary hypomorphic LEPR-B mutations are perhaps the most straightforward to classify, because such individuals have cellular leptin resistance in its purest form and there can be no question that the failure of cellular leptin action is causal to the obesity pathogenesis in these animals. Similarly, it is possible to link alterations that compromise LEPR-B trafficking or downstream LEPR-B signaling (e.g., interference with LEPR-B → STAT3 signaling, activation of inflammatory signals) [36,39–41] to obesity arising as a primary consequence of cellular leptin resistance. In each of these cases, diminished LEPR-B signaling (e.g., pSTAT3) and leptin action is observed under all conditions.

Disruption of neural pathways participating in leptin action

For disruption of neural pathways involved in leptin action, the hypothalamic melanocortin system affords an informative example. In this system, propiomelanocortin (POMC) neurons in the arcuate (ARC) nucleus of the hypothalamus project to downstream targets (such as the paraventricular hypothalamic nucleus; PVH) where they release POMC-derived peptides, including α-melanocyte stimulating hormone (MSH), which activate CNS melanocortin receptors to reduce food intake and increase energy expenditure [42,43]. Many ARC POMC neurons express LEPR-B, and leptin increases the activity of the melanocortin system. Disruption of melanocortin action by physical lesions of the ARC or PVH, by pharmacological means, or by various genetic alterations at the level of the melanocortin peptide or its receptors, causes obesity and proportionate hyperleptinemia. In the case of such disruptions (for instance, in the case of animals null for the melanocortin 4 receptor [44]), obese animals display cellular leptin resistance and severe attenuation of leptin action on feeding, whereas pre-obese animals will have normal cellular LEPR-B signaling and only modestly diminished leptin action on feeding and body weight. Terming this form of obesity ‘leptin resistance’ obscures a great deal of mechanistic detail regarding the primarily affected (e.g., melanocortin) pathway, which lies downstream of cellular LEPR-B signaling/action.

Alterations in peripheral tissues that operate independently of food intake

Under certain conditions, genetic alterations that affect energy metabolism in peripheral tissues can promote increased adiposity. For instance, disruption of mitochondrial uncoupling protein (Ucp)1, which mediates a mitochondrial proton leak to convert fat energy to heat in brown adipose tissue, diminishes energy expenditure and promotes increased adiposity in animals housed at thermoneutrality (although these effects are difficult to detect under other conditions) [45,46]. Although the potential ‘leptin resistance’ of such animals is rarely examined (why would this be done, given that the lesion clearly lies outside of the leptin pathways?), the prediction is that these animals should exhibit a blunting of cellular leptin action and leptin effects on feeding when studied in the obese state, but that both should be normal in the pre-obese, lean state.
Alterations in CNS pathways with no clear link to leptin action

Alterations in CNS pathways without a clear primary relationship to leptin action include impairment of brain-derived neurotrophic factor or its receptor (TrkB) [47,48], disruption of pathways involved in Bardet–Biedel syndrome [49], Prader–Willi syndrome [50] and other obesity-provoking genetic alterations. Although the cellular and anorectic response to leptin under the obese condition in these models can be expected to (and does) reveal cellular leptin resistance and decreased leptin action on energy balance [49], such studies do not address whether this impairment is secondary to obesity, or whether it occurs independently of obesity and might thereby contribute to obesity pathogenesis. Testing for a primary defect in cellular LEPR-B action (presenting as decreased pSTAT3) that operates independently of obesity can shed light on which comes first, the leptin resistance or the obesity. The observation of partial reduction of food intake in response to leptin in the presence of normal LEPR-B signaling requires cautious interpretation, however, as this might reflect disruption of either leptin-regulated downstream neural pathways or other neural systems that modulate feeding.

In summary, although mechanisms of cellular leptin resistance are likely to have important implications for energy balance, it is important to distinguish cellular leptin resistance that is caused by obesity from the often distinct primary processes that promote obesity in genetic (and other, e.g. diet-induced) models. The value of obese genetic models lies in the identification of the underlying molecular mechanisms that control energy balance and that, when defective, can cause or predispose to obesity. To effectively determine the potential primary effect of a genetic lesion on leptin action itself, the assays must be performed in non-obese animals.

The elephant in the room: cellular leptin resistance in context-dependent obesity, including DIO

Although genetic alterations in humans and animals have taught us a great deal about mechanisms of severe obesity and the systems that govern energy balance, it appears that the changed environment, not altered genetics, underlies the burgeoning epidemic of obesity in developed and developing countries. During the past 50 years, two major changes have shifted the energy balance equation: the decreased requirement for physical energy expenditure and the increased availability and abundance of palatable, calorically dense foods. A common research model of obesity investigators, DIO, mirrors the ubiquity of highly palatable, calorie-dense foods in modern societies. In this paradigm, animals remain lean when maintained on standard chow, but increase their caloric intake and rapidly gain adipose mass when provided a calorically dense diet (generally high in both fat and sugar content). Although genetic predisposition to DIO clearly exists (some rodent strains gain little weight on high-calorie compared with normal chow, whereas others rapidly progress to obesity) [51], it is the availability of a highly palatable diet that drives overeating and subsequent obesity in these models.

It is debatable as to what extent cellular mechanisms of leptin resistance (i.e., impaired LEPR-B and downstream signaling) cause and/or facilitate the obese phenotype in DIO models. Clearly, we cannot resort to examining adiposity-matched animals on each diet (as one could for genetic models), because the major factor driving the body weight difference between DIO and Chow-fed lean animals is the hedonically driven excess consumption and consequent adiposity, rather than an innate difference of leptin signaling. How then to distinguish the causes from the consequences of obesity?

Perturbing the known mechanisms of cellular leptin resistance has provided some insight here, because interfering with neuronal LEPR-B Tyr985/SOCS3, PTP1B, ER stress and some inflammatory pathways protects against obesity and augments the response to exogenous leptin in animals fed highly palatable diets [27–29,35,36]. The development of cellular leptin resistance with increasing obesity in DIO limits the ability of leptin to control adiposity, thereby magnifying the extent of weight gain or, to be more specific, participating in the determination of the new level of body fat stores following the change in diet.

To what extent might cellular leptin resistance function as a primary factor in weight gain in DIO? In fact, several lines of evidence argue against such a causative role. First, although the pSTAT3 response to exogenous leptin might be diminished in DIO animals, baseline ARC pSTAT3 levels in the absence of exogenous leptin administration (i.e., LEPR-B signaling due to endogenous circulating leptin) are actually increased in DIO animals compared with Chow-fed controls [23]. Thus, the reduction in LEPR-B signaling observed with exogenous leptin administration reflects a response to pharmacologic manipulation; although the mediators of cellular leptin resistance might restrain LEPR-B signaling in obesity (i.e., baseline pSTAT3 in DIO animals should perhaps be higher in the absence of cellular leptin resistance), these mechanisms of cellular leptin resistance do not reduce LEPR-B activity to levels below those in Chow-fed animals and thus cannot account for DIO on their own. Second, DIO animals tend to reduce their food intake and body weight when switched to a less palatable diet [52]. Hence, the presence of cellular leptin resistance in DIO animals is insufficient to maintain the full obesity phenotype in the absence of the primary precipitant (palatable high-calorie Chow).

We propose that increased food intake and associated adiposity promotes cellular leptin resistance in DIO and that this cellular leptin resistance prevents LEPR-B signaling from reaching the level that it would otherwise attain in response to the increased ambient leptin, thereby further facilitating the weight gain associated with the consumption of a high-calorie diet. This model has the advantage of incorporating the potential relevance of cellular leptin resistance in the pathogenesis of common forms of obesity while acknowledging that it cannot explain the entire pathogenesis of DIO. It also recognizes the potential for mechanisms of cellular leptin resistance as therapeutic targets, because mitigating these processes should enhance LEPR-B signaling, thereby reducing the degree of obesity.

The initiation of DIO

What are the key mechanisms that drive the development and maintenance of obesity in DIO? Many factors can affect
food intake, only some of which are subject to biological regulation and the amount of food that is ultimately consumed represents the integrated effect of these factors (Figure 2a). Tending to increase food intake are the hedonic attractiveness and availability of food, learned preferences and molecular mediators of hunger, such as ghrelin and cannabinoid signaling (as well as relative reductions in ambient leptin levels with weight loss) [2,3,53–55]. Opposing these factors are leptin action and other mediators that promote satiety, including insulin and numerous gut-derived signals. Altering the strength of, or sensitivity to, any of these factors will alter the amount of food consumed and hence affect adiposity. Just as decreasing the strength of the leptin signal will increase feeding by diminishing anorectic drive, so will increases in the palatability and/or availability of food, even when the cellular efficacy of leptin signaling remains unchanged.

Hence, in DIO (and presumably in much of human obesity), the presence of palatable food favors an increase in food intake; as this increase in feeding causes fat stores to increase, the resultant rise in signals of energy repletion (including leptin) will eventually favor the return of food intake toward levels matched to energy expenditure, creating a new steady state (albeit at the price of higher adiposity) (Figure 2b and 2c). Indeed, when rodents are switched to a high-calorie diet, their energy intake initially increases dramatically, followed by a gradual return toward baseline values (normalized to metabolic mass). This return toward baseline feeding reflects the establishment of a new equilibrium at which the heightened incentive to feed mediated by the palatable food is balanced by the effects of increased anorectic signals such as leptin and gut satiety signals. Thus, increased adiposity is a predictable response to the enhanced palatability of available food, even in the absence of molecular and cellular pathways that might interfere directly with leptin signaling and action.

An important corollary in this context is that if the diet-promoted increase in adiposity also induces cellular leptin resistance, the amount of circulating leptin needed to achieve this new equilibrium is proportionately increased and this increase must occur through the further expansion of fat mass. Hence, diet-induced cellular leptin resistance leads to the defense of an even higher level of body fat stores than would otherwise occur. Thus, although cellular leptin resistance is not the primary cause of weight gain in this scenario, it influences both the amount of weight (fat) gained and possibly the subsequent defense of that elevated weight. Removal of the palatable food diminishes the strength of the orexigenic drive, allowing the now elevated (secondary to increased adiposity) leptin action to drive feeding down towards a new equilibrium value. The extent of weight loss will therefore depend on the associated diminution of cellular leptin resistance and other processes that are induced during the adaptation to obesity, with the consequence that normalization of body weight upon the removal of palatable, calorically dense food might be incomplete.

With this background, we return to the issue of whether DIO can aptly be described as a state of leptin resistance. We suggest that this description is appropriate when referring to mechanisms that limit cellular leptin action

Figure 2. Determination of the settling point for food intake. (a) Mechanisms that contribute to food intake, with those factors that exert pressure to decrease feeding listed on top and those that tend to increase feeding listed on the bottom. (b) Initial response to increased palatability/availability of food, which increases feeding by increasing the drive to eat. (c) New equilibrium for food intake in the continued presence of increased food palatability/availability. Increased feeding promotes increased adiposity, which increases leptin action to promote earlier satiation and additional effects to decrease feeding toward the initial baseline. With obesity, cellular mediators of leptin resistance are promoted in the hypothalamus, limiting leptin action and increasing the amount of leptin/adiposity required to suppress feeding.
themselves, but that it is essential to distinguish this phenomenon from the initiating insult (e.g. palatable food, the genetic lesion predisposing certain animals to obesity), which might not, in and of itself, impair LEPR-B signaling and cellular leptin action.

**Obesity and the notion of ‘selective’ leptin resistance**

It has been proposed that the maintenance of reproductive function, energy expenditure, sympathetic outflow and other leptin-regulated processes in the setting of DIO indicates impaired leptin action in obesity, restricted to the control of feeding. Note that although the effect of genetic lesions that impair specific leptin-regulated pathways might produce selective leptin resistance, these represent a different case from that of DIO [39,56]. Several lines of evidence argue against a meaningful selectivity in leptin resistance in DIO. First, a variety of data suggests that leptin acts on both energy expenditure and feeding via overlapping sites and mechanisms [43,57] and the nature of a process that might interfere with feeding but not energy expenditure is thus unclear. Indeed, although the ARC represents a major site of cellular leptin resistance in DIO [23], ARC leptin action modulates energy expenditure, glucose homeostasis and other aspects of leptin action in addition to participating in food intake. In addition, endogenous leptin clearly plays a role in limiting appetite in DIO, as food intake rapidly restabilizes after the initial increase of feeding on highly palatable, energy-dense chow. Indeed, increasing the palatability of food promotes increased food intake despite the integrity of cellular leptin action, although food intake returns toward normal as adiposity increases (with the attendant increase of leptin levels and action) (Figure 2). The decrease of feeding and body weight upon the reinstatement of a normal chow diet suggests that the initial increase of food intake and subsequent adiposity represents a predictable response to the hedonic characteristics of the novel diet, rather than a response to diminution of leptin action. Thus, the transient increase and subsequent return of energy intake toward baseline during DIO support a model in which elevated leptin action during obesity contributes to the control of hunger as well as energy expenditure. Furthermore, the response of obese humans to weight loss (which causes responses such as increased hunger, cold intolerance, and decreased thyroid and sympathetic tone) is fundamentally intact [12], suggesting that the ‘extra’ leptin in obese individuals exerts biologically relevant effects on parameters additional to those involved in the control of feeding. If it can be postulated that the effect of weight loss from the obese state is to increase hunger and that this reflects ongoing leptin resistance, the same must also be true for the other factors (diminished thyroid tone, cold intolerance and so on) that also accompany weight loss. Thus, a variety of data argues against a meaningful selectivity (i.e. control of feeding only) in the attenuation of leptin action in DIO and common human obesity.

**Potential mechanisms contributing to the maintenance of obesity with dietary intervention**

If much of the obesity in developed societies represents a response to plentiful, available and palatable food, why does the withdrawal of such foods, as occurs with dieting, generally fail to achieve sustained weight loss in obese individuals? This is a difficult issue to investigate in humans, because palatable foods are readily available and virtually omnipresent, even to most dieters; a tasty, calorically dense treat is only as far away as the nearest refrigerator, vending machine, convenience store or dessert menu. This ubiquity of palatable, energy-dense foods probably contributes to the failure or relapse of many dieters, especially as weight loss itself potently increases the drive to eat.

To control for the vagaries of food availability, obese individuals have been hospitalized for study. When subjected to a weight loss of 10% or greater (to within the high–normal weight range), such patients exhibit decreased thyroid and sympathetic tone, cold intolerance, and increased hunger [12,58]. Because these effects are reversed by the administration of low dose exogenous (replacement) leptin, many of these changes are attributable to the associated decreased circulating leptin concentrations that occur with weight loss. Thus, decreasing leptin concentrations from obese values provokes a physiologic response that tends to defend the obese levels of adiposity.

This adaptive response to weight loss (or rather, to the associated decrease of circulating leptin) could theoretically reflect a different baseline settling point (‘threshold’ for leptin action) in individuals who are predisposed to obesity or, alternatively could indicate that obesity and/or hyperleptinemia induce longer-term changes in neural systems that modulate energy balance, which, in turn, resets the system to a new and elevated defended level of adiposity. These possibilities are not mutually exclusive.

In at least some rodent models, the restoration of normal chow to DIO animals reduces food intake and adiposity [52], but not necessarily to the levels observed in animals that were never exposed to the obesogenic diet. Once obesity becomes established, therefore, an upward re-regulation of the defended level of body fat stores might occur. Indeed, there exist several otherwise confusing observations that can be accounted for by proposing that long-term reprogramming occurs in chronic obesity/hyperleptinemia. One example is the finding that chronic leptin overexpression in rodents, which initially promotes leanness, results in increased adiposity in the long term [59–61]. How the homeostatic system might become reset to a new and elevated level of adiposity and/or ambient leptin remains a key open question. Although many components of cellular leptin resistance would be expected to diminish with decreasing adiposity (e.g. the activation of Tyr985/SOCS3-dependent feedback inhibition), other contributory processes might be relatively fixed and, hence, more difficult to reverse.

**Important issues for obesity research**

One implication of the foregoing discussion is that the potential causes of common obesity are myriad. Indeed, recent genome-wide association studies (GWAS) have identified common polymorphisms at numerous loci, each with very modest contributions to adiposity [62]. The common polymorphisms/loci identified to date collectively account for little more than 10% of the heritable predisposition...
to obesity, consistent with the notion that the genetic variability in obesity susceptibility probably represents the sum of multiple small changes, each of which affects different molecular determinants of feeding (or potentially energy expenditure). These GWAS focused on alleles with >5% frequency in the studied populations; hence, it remains to be seen whether lower frequency alleles of the same and/or other genes can account for the remainder of the genetic susceptibility.

Genetic differences affecting neural pathways controlling the perceived reward value of food can be expected to modify the magnitude of the response to a change in the type or availability of palatable foods. Such gene variants might be among many factors that influence this response, including, for example, developmentally encoded differences in the function of the ARC melanocortin pathway; sensitivity to meal-related satiety signals; variation within pathways involved in cellular mechanisms of leptin action or resistance; and learned preferences (and the factors that underlie them). Genetic differences in the leptin receptor and its signaling pathway could also play a role in affecting obesity risk, by promoting cellular leptin resistance, although minimal genetic data currently exist to support this mechanism (with the exception of a potential role for SH2B1, a LEPR-B-associated signaling molecule that promotes leptin action and for which common polymorphisms are associated with obesity in GWAS) [63,64].

Along similar lines, there are many potential ways to lower food intake so as to achieve therapeutic benefit. A sustained increase in the strength of anorexigen signals will favor the maintenance of a reduced level of body fat stores, as would interference with orexigenic signals and mediators of cellular leptin resistance; intervention at multiple independent points is likely to produce synergistic effects. Hence, many systems deserve a more detailed integrated analysis as we seek to better understand the mechanisms governing food intake and to modify them therapeutically, including the neural pathways that modulate food palatability and reward. It will also be important to clarify how physiological signals, including leptin and ghrelin, interact with these brain systems to modulate the hedonic drive to eat. Similarly, nutritional status and hormonal cues such as leptin and ghrelin are now recognized to affect behavior and emotion beyond feeding, including anxiety-related and depression-related behaviors [65,66]. It will therefore be useful to improve our understanding of these pathways and gain mechanistic insight into how mood contributes to overeating and/or eating disorders (and vice versa).

Beyond changes in diet and lifestyle, it is clear that other environmental influences can also modulate the predisposition to obesity. Perinatal nutrition and other exposures contribute to the lifelong risk for obesity and metabolic disease [67]. The mechanisms by which the early environment programs the later metabolic outcome remains unclear, although imprinting of key genes or altering the architecture of the neural circuits that control feeding and energy expenditure (or both) represent reasonable possibilities. The mechanisms and consequences of these developmental perturbations represent important avenues for future research.

Lastly, much remains to be learned about mechanisms underlying cellular leptin resistance and the relative importance of various mediators of cellular leptin resistance. Major issues in this area include mechanisms by which overfeeding and obesity promote ER stress and inflammation in key neuronal subsets, and how mechanisms of anorexigenic (e.g. sepsis) and orexigenic (associated with cellular leptin resistance) hypothalamic inflammation differ in terms of their amplitude, timing, molecular pathways and cell specificity. Related questions pertain to roles for specific nutrients (e.g. fatty acids) in cellular leptin resistance in the hypothalamus, and much remains to be learned about the importance of such processes in obesity-associated attenuation of leptin action. It will also be crucial to determine whether and how chronic obesity and/or hyperleptinemia promotes a durable program to reset the neural expectation for higher levels of adiposity (e.g. leptin), which could occur at the level of cellular action, neural circuitry/plasticity, genomic imprinting, or other processes. In this context, it is important to consider that not all such obesity-induced mechanisms that promote feeding and/or interfere with anorectic processes will necessarily alter LEPR-B signaling. If and when such processes are identified, it will be important to label them in precise, mechanistic terms, rather than grouping them together as ‘leptin resistance.’
